Abstract
Science monitoring is a core issue in the new world of business and research. Companies and institutes need to monitor the activities of its competitors, get information on the market, technologies, or government actions. This paper presents the Tétralogie platform that aims at allowing a user to interactively discover trends in scientific research and communities from large textual collections that provide geographical location. Tétralogie consists of several agents that communicate on users’ demand in order to deliver results to them. Meta-data and document content are extracted before being mined. Results are displayed under the form of histograms, networks and geographical maps; these complementary types of presentations increase the possibilities of analysis compared to the use of these tools separately. We illustrate the overall process through a case study of scientific literature analysis and show how the different agents can be combined to discover the structure of a domain. The system predicts correctly the country contribution in future years and delivers the relationships between countries.

Key words: information mining, data analysis, domain knowledge, knowledge discovery, information visualization, geographical maps

1 INTRODUCTION

Competitive intelligence is a core issue in the new world of business and research. Companies and institutes need to monitor the activities of its competitors, get information on the market, technologies, or government actions. These monitoring activities are necessary for them to define alliance strategies, innovation and customer oriented strategies. Organizations need methods and tools to lead such activities, that gather information, mine them and display the results in a friendly and efficient way. Large-scale analysis becomes possible thanks to the availability of large sources of publication, patent, scientific literature (Buter, 2002), and other data available in electronic form.

Analyzing scientific publications to discover trends and to know the structure of a scientific field and the evolution of scientific communities or topics have been widely explored in the literature, specifically -but not exclusively in scientometrics (Leydesdorff, 1995). Different types of analysis can be done. In information science, citation and co-citation analysis have been studied in the past as a way to monitor scientific activities (White and McCain, 1998), (White, 2003). Citation analysis is used to identify core groups of publications, authors and journals. ISI Web of KnowledgeSM®2 for example uses citation analysis to determine the history of journal's citation and authors. In the same way, hypertext references are mined in the web context, to determine the authority of the pages and to re-rank retrieved pages (Kleinberg, 1998). On the other hand, co-citation analysis3 is used to detect networks of authors or to map topics and authors or journals (Zitt and Bassecoulard, 1994) (White, 2003). CiteSeer4 provides a reference to related documents from co-citation. Other digital libraries provide a cross access to related documents. DBLP5 for example provides a co-author index that gives access to the co-authors’ publications or collaborative colleagues as the ACM Portal6 does.

Digital libraries usually deliver the results under the form of lists of related elements (list of related publications or authors) even though it had been shown that graphical interfaces play an important role to display the results of analysis to users (Chen, 2002), (Geroimenko, 2002). In that context, graphs or networks are powerful techniques of

5 http://www.informatik.uni-trier.de/~ley/db/index.html
6 http://portal.acm.org/
visualization mainly because linking concepts or elements together is the most common mining technique. Another reason is that a network is easily understandable even by a naïve user.

When analyzing a word-wide phenomenon, such as scientific activities, mapping topics and countries or detecting core sets of countries or regions allows one to detect important trends. Geographic maps are the most intuitive way to describe and explain the spatial organization of a phenomenon that involves geographic referenced data, that is to say data which has location reference within its structure. Geographic map as a way to communicate information to users by visualizing database-type information is powerful (Ahlberg & Shneiderman, 1995), but not enough.

We argue that combining geographic maps, mining tools and other visualization modes interactively is much more powerful. In our approach, geographic maps are used to display the results of an analysis to the user. More importantly, at any step the user can interact with the visualizations to filter the information (changing his focus) and visualize the selected information using another visualization mode or mine this targeted information. This method implements a powerful and interactive discovery process. This process can be applied to any type of textual information even if heterogeneous in terms of format (structured documents -different structures- such as INSPEC documents, or semi-structured documents such as web documents). Our contribution is intended to help scientists and deciders to easily have a large and interactive overview of a specific domain knowledge related to research and technologies. More precisely, it helps them to grasp strategic key factors –actors, actions, relationships and dynamics- of the domain. It also help in the process of elaborating hypotheses add assessing them- e.g. by visualizing raw information: that supports a hypothesis.

In this paper we present the model we use to represent the information in such a context. We also present the different agents of our system and the way they interact to implement a powerful discovering process. We illustrate the overall process using a case study based on scientific papers from SIGIR (Special Interest Group on Information Retrieval conference).

The paper is organized as follows: section 2 presents related works. Section 3 describes the case study. Section 4 describes the way information is represented in order to be in a format that can be efficiently analyzed, example from the case study are given. Section 5 presents different mining functions that are implemented in the platform; their
usefulness is illustrated through the case study. It also presents the graphical view modules that users are provided with, also illustrated through our case study. Section 6 describes how the different agents communicate in order to discover additional advanced information. We conclude this paper and present future works.

2 RELATED WORKS

The system we present and the underlying knowledge discovering process combines Data Mining (DM) and Geographic Information Systems (GIS) functionalities in order to analyze scientific domains from publications.

GIS is a computer system to handle geographically referenced data, that is to say data that is described in terms of location (for example, spatial co-ordinates measured in degrees latitude and longitude) or characteristics of spatial features (for example an address). DM on the other hand aims at discovering unknown information from data by applying mining functions such as classification, clustering, or detection of dependencies, etc. Combining these two approaches is important because of the quantity of spatial data available (Buttenfield et al., 2000).

Different softwares combine mining and GIS functionalities. GeoMiner (Han, 1997) extends DBMiner (Han, 1997) to geo-referenced data. Initially, DBMiner mines databases using multi-dimensionnal analysis (Widom, 1995). Combined with MapInfo software, it is now possible to mine data that includes a geographic dimension. The analysis can be done at different level of details (state, country, etc.). (MacEachren, 1999) also investigated the integration of data mining and geographic visualization in the context of spatiotemporal environmental data. (Gahegan, 2002) presents GeoVISTA studio, an environment designed for handling geospatial data. It can be used to build applications for geographic visualization that can combine different mining tools. In the same way, Descartes (Andrienko, 2000) is associated to Kepler system to visualize statistical information such as election results, demographic data, etc. Like in Spotfire (Ahlberg & Shneiderman, 1995) formerly known as IVEE, databases content can be visualized using a variety of visualization tools.

Analyzing textual documents and their geographic dimension has been studied in different approaches. In (Verbeek, 2003), the authors present an analysis of patents. They analyze the geographic distribution of the science citation patterns including the flows between the regions. In (Doré, 2001) publications by 48 countries in 18 disciplines over 12 years have been analyzed. In (Mothe, 2003) a large set of documents
is analyzed using on-line analytical process considering different document dimensions, one of which being location. The methods used in these different approaches do not combine mining techniques and GIS functionalities. As a consequence the discovered information is not easy to visualize according to location. Visualization tools when analyzing a domain is a key issue. (Boyack, 2004) reports a study on melanoma and the structure of the research on this topic from MedLine publications. Similarities between different element types, papers, genes, and proteins are calculated and the results are displayed under the form of networks using force-directed placement.

In (Skupin, 2004) and (Skupin & Fabrikant, 2003), the authors propose a method to map knowledge domain using self organized maps and use a nice metaphoric geographic language to depict to the studied domain. The input data are abstracts from scientific papers (abstracts submitted to the annual meeting of the Association of American Geographers). Unlike us the authors do not take advantage of the multi-facetted of the documents (namely titles, authors names, addresses … ). Also, apart an interesting “semantic zoom” tool, the visualization model used is quite static.

In our approach, geographic maps are more than a metaphor. They are used to display results of data mining that implies a geographic dimension. Moreover geographic maps interactively changed according to messages delivered by other visualization modules or mining modules (implemented as agents). This feature is used to handle temporal geo-referenced data as well as to give focus to some target data.

3 PRESENTATION OF THE CASE STUDY AND APPLICATIONS

We will illustrate the document mining process for domain analysis using a simple case study. The document set we chose should be considered only as a pedagogic illustration of the overall discovery principle. The system has been successfully used for competitive intelligence and science monitoring and evaluation purposes since 1991 in its earlier versions. Among real studies that have been conducted using the system, we can quote: Analysis of the TPV department (Plant Health and the Environment Department) of the French INRA institute (National Institute for Agricultural Research) (2002), Evaluation of INRA research in the domain of ecology, environment and engineering (2003), Study on OMEGA 3 for Fabre laboratories. Study on the management of pesticide Gaucho ® crisis (2004). We carried out four health related studies for Health and Medical Research National Institute (apatite, apoptosis, flu, and epilepsy). For the French ministry of defense, we carried on analysis on the following
topics: steel, information war, nuclear power, scientific literature on sub-marine detection.

However, the results of these studies are confidential and a simpler set of documents is enough to understand the power of the methodology used.

The set of documents we chose to illustrate the paper is composed of the long papers published in SIGIR conferences. This information has been extracted from the ACM Portal (see figure 1). In this paper we will use two document sets. One is composed of recent papers from 2000 to 2003 and consists in 173 papers in total. The second set is composed of the papers from 1991 to 2002 and consists in 440 papers.

Figure 1: Harvesting documents from ACM Portal.

As we say previously, we chose this set in order to illustrate our methodology; however this methodology is not context dependent and thus can be applied to any type of documents from any domains.

Regarding geo-related information, the type of advanced information that can be discover ranges from the main actors in terms of location of a domain (countries, laboratories or institutes), the specificities of a location (according to a domain, what are the sub-topics that characterize one location) and their evolution, links between location and dependencies including strength of the links regardless either concrete collaboration
To make possible such analysis, a common representation of the information is adopted. The way we represent textual information and location is explained in the next section.

4 INFORMATION REPRESENTATION

4.1 Multi-dimensional representation

Document facets

Documents and texts express a vast and rich range of information that traditional information indexing does not take into account (Hearst, 1999). Indeed, usually in information retrieval applications, documents are viewed as bags of weighted words (Rijsbergen, 1979). That means that document indexing results in a multi-dimensional information space representation based on a single facet - the free-text content facet. As a result, the semantics of the information is diminished. To solve this problem, we promote an approach in which documents are represented in a multifaceted multi-dimensional space (Mothe, 2003). In this multi-dimensional representation, each facet corresponds to a point of view that may be of interest for the user to which a semantic is associated. Indeed, when considering a document as a bag of words, each term is considered the same way. For example, the author of the document will be considered as any term of the text content. On the opposite, when considering multifaceted multi-dimensional representation as we suggest, each term is related to a context (facet) and thus carries more semantics. Facets can be viewed as “meta dimensions”. In the rest of the paper the word dimension refers to facet.

One of the important dimensions corresponds to the geo-reference(s) associated to publications and corresponds to the producer(s) of the publication. This dimension is organized along a hierarchy of concepts (specificity/genericity relationships). One level of the hierarchy is the institutes/organizations level. The upper level is countries then continents. Institutes can be defined by their spatial co-ordinates whereas the other levels are areas defined by their borders. The levels of the hierarchy are set ones for all. For each document, its geo-reference information is extracted from the head of the document using the principal explained section 4.2. In the multi-dimensional representations we propose concept hierarchies related to each dimension can be handled. This is a more general approach than the idea of ‘simple’ concept hierarchies
developed by J. Han (Han 1994, 1995). In fact there are two levels of concept hierarchies which are related to the following:

- Dimensions: each sub-concept defines a sub dimension. For example Authors can be split into two sub-dimensions which are “principal authors” and “collaborating authors”. Another example is the key words dimension which can be split into major key words” and minor key words –as in Medline the bibliographic database from the National Library of Medicine where descriptors are split into major and minor descriptors.

- Content: the content of a dimension can be organized along a concept hierarchy (this is the common approach).

Note that hierarchies of content can always induce hierarchies of dimension but the opposite is not true, as in the two examples given above. Hierarchies of concepts related to dimensions are then a more general approach.

The geo-references associated to a document are not the only dimension we are interested on. Other document dimensions are “temporal references” (date of publication), “content” (which can be in turn declined into several points of view or sub-dimensions such as techniques used, names, locations, etc.). In some domains, pre-defined ‘content’ dimensions exist. In such a case, we simply use them. This is the case for example in medicine (Medical Subject Headings7 Hierarchy) or in astronomy (IAU thesaurus8) or many other domains. In the case an ontology of the domain exist, we infer a hierarchy from it (Aussenac, 2004) before using it. In the other cases –no hierarchy of concept is associated-, we simply extract the most discriminating terms using traditional indexing techniques (Frakes, 1992). In that later case, the resulting dimension is flat. This is also considered as an explicit dimension of which Authors is an example. Implicit dimension are the ones generated from a dimension hierarchy of concepts.

The multi-dimensional representation has several advantages. Firstly, as we said before, each term corresponds to a context. For example, given an institute name in the 'producer of publication' hierarchy, it corresponds to the institute an author belongs to and not a name of an institute that is used in the content of a publication. Secondly, it is possible to associate documents to these hierarchies in an automatic way as it is presented section 4.2 (this can help answer questions such as what are the institutes a

7 http://www.ulst.ac.uk/library/sci/MeSH.htm
given group of authors belong to? and which countries are related to a given institute?). Finally it is possible to browse and mine a collection of documents that is represented in this way.

**Facets regardless the case study**

A document as provided by ACM portal contains different types of information that can be extracted: the source, the title of the publication, its authors and affiliations, the ACM index terms and the publication abstract. According to this case study, different facets have been defined:

- **Producer:** at the most specific level it corresponds to the author names whereas at the most generic level it corresponds to the continent of the author's affiliation.
- **Topic:** it corresponds to the concepts contained in the publications. Here we extract the topic from the title and the abstract. As a result this point of view is flat. However, we could have used the concept hierarchy provided by the ACM portal (index terms).
- **Time:** it corresponds to the publication date. Because SIGIR is an annual conference, in that case the lower level of granularity of the information is the year.

### 4.2 Mapping documents and generating points of view

Information extraction and document categorization techniques are used in order to map documents into each dimension (either explicit or implicit). After analysis, a document is represented by several sets of 'values' -or 'dimension instantiations'- that corresponds to concepts from each dimension. For example, considering the 'producer of the publication' point of view, a document that has two institutions as “authors” will be associated to two nodes (instances) of the institute level -the hierarchy corresponding to that point of view. Implicitly, this document will also be associated to the parent nodes of these two institute-nodes (in our case the organizations they belong to).

**Information extraction: mapping documents and hierarchies**

According to our approach, a document is described according to a schema of extraction. The *schema of extraction* is the complete meta-description of the document set; that is to say all dimensions that can be used from the documents. The schema also describes the way the values of these attributes can be extracted according to the source.
This schema has to be sufficiently formal to be source independent and yet sufficiently functional to be used in real applications to extract whatever dimension instantiations. Thus, the main purpose of the schema of extraction is to provide a description on how the useful information is to be extracted from a document set. The schema is fully defined by the five following components:

- The schema of extraction describes and uses the explicit structure of the document set. This defines the initial structure of documents that is to say meta-data that is marked-up in the document source,
- The schema of extraction defines the implicit extraction structure: This structure defines the list of useful dimensions that can be processed and their relationships to the explicit structure,
- The schema of extraction lists the extraction rule set which describes how these dimensions instances can be extracted according to the structure of the document set, (template filling out)
- The schema of extraction instantiates semantic functions for each dimension. These functions are used to solve semantic conflicts -like synonymy- among the set of values of each dimension ,
- The schema of extraction also instances filtering functions: these functions permit to focus on a reduced set of values when dealing with a given dimension –e.g. stop lists, important concept instances.

For more details of our information extraction model see (Chrisment et al., 1997).

Note that this approach allows the handling of both structured document and non structured document sets. In the case of non-structured element of information, we use categorization techniques in order to map documents and hierarchies. Concept hierarchies and documents can be associated in an intuitive way by considering each concept of the hierarchy as a category. Some approaches have been proposed in order to consider the hierarchical structure of the categories as opposed to a flat categorization (Weigend, 1999). We developed our own method to associate a document to the concepts from the different concept hierarchies in which the hierarchical structure is taken into account (Mothe, 2003). In our model a document can be associated to several hierarchies and to several concepts through the use of semantic and filtering functions describes above.

4.3 Information summarization

A document collection is summarized under the form of 2D matrices for which each matrix columns or rows correspond to a dimension instantiations -filtered and reformulated using associated semantic and filtering functions. These matrices correspond to co-occurrence matrices. In the specific case where different dimensions are considered, the matrix is a contingency table. Contingency tables are efficient to represent summarized information (Zembowicz, 1996). In addition, many data analysis methods use matrices or contingency tables as entries. Clustering or other methods can thus be applied as explained in section 5.

Because the points of view are hierarchical, it is possible to consider the 2-D tables at different levels of detail using roll-up and drill-down operators as defined in OLAP systems (Widom, 1995), (Chrisment et al., 2003).

For example, figure 2 presents the results of crossing publication producers (lines) and years (columns) on the case study. The contingency table depicts the number of publications of each 'category'. A publication for which an author is from China is counted as a publication from ASIA.

![Figure 2: Extract of a 2D-summarization structure using the producer (geo-reference) and temporal reference points of view from the case study.](image)
5 INFORMATION MINING AND VISUALIZATION AGENTS

Different kinds of mining methods have been defined in the literature that can be applied on contingency tables or tables derived from them. We do not define new methods but rather lean on existing analysis methods. However our contribution is to implement them as agents that collaborate to provide synergy in the process of discovering information. Another contribution is to associate these functions with powerful visualization tools. Agents communicate on users’ demand to provide the other agents the discovered information as described section 6.

In this section, we present only some of the functions, but other functions are implemented. Among these functions, we will present the spreadsheet functionalities and associated tools, the agglomerative classification and the network agent. We will also present the map visualization agent. For each of them, we will present one example of its usefulness when analyzing a set of documents.

The platform is also composed of different visualization tools: spreadsheet, histograms, graphs, 4D-views and geographic maps. These agents communicate with the mining agents and with each other, in this latter case mainly to compare their results views.

5.1 Spreadsheet agent

Functionalities

A spreadsheet agent is implemented. It allows one to manipulate directly the 2D tables. This agent offers to the user the main spreadsheet functionalities (deleting, adding columns and rows, reordering of rows and columns according to the cells’ values, operation on the values such as mean, additions, histograms, etc.).

This agent is used in order:
- To obtain normalized data when the initial data is not e.g. dividing the values by the sum. E.g from a table that cross authors-rows and dates-columns, dividing the row-values by the sum of these values allows one to get the relative contributions of the authors.
- To detect the most frequent items (figure 3a).
- To detect evolution in data. E.g; from a table that crosses countries and years a histogram on a specific country allows one to visualize the evolution of the publication activity (figure 3b to d).
Spreadsheets to discover evolution of the countries contribution

In this example, we consider the second set of document (from 1991 to 2002) for analysis and the data from 2003 to validate the prediction our system does.

The system provides a table that crosses countries and dates. In this sample of documents, 12 years and 31 countries occurs at least once. A paper that is co-authored by people from two different countries will be counted twice.

<table>

</tbody>
</table>

<table>
<thead>
<tr>
<th>a) Number of paper per countries and per year</th>
</tr>
</thead>
<tbody>
<tr>
<td>b) Evolution of the publication number for Israel</td>
</tr>
</tbody>
</table>
Regarding the contribution of the USA, the system indicates their level of publication is stable whatever the year. It is possible to predict this will continue. Indeed USA published 26, 23 and 25 papers respectively in 2001, 2002 and 2003.

Finally, considering Switzerland, the system predicts the contribution to SIGIR of this country is decreasing. There is no publication in 2003.

5.2 Classification methods

2D summarization structures as defined in section 4.3 fit well classification methods, it is possible to group together items (lines) according to characters (columns). The platform includes two types of classification agents: the Agglomerative Hierarchical Clustering (AHC) and the Classification by Partition.

Agglomerative Hierarchical Clustering

A HAC is used to classify the elements according to their similarities. Two classes are grouped together if they are the closest couple of classes. At the beginning of the
process, each element corresponds to a class. The process ends when the target number of classes is reached.

This mining function is useful when one wants to detect elements that follow the same behavior. For example, it can be used to group together laboratories that have the same topics of interest (working on the same areas). In that case the source table would cross topics and laboratories.

**Classification by Partition (CbyP)**

A CbyP is a non hierarchical and supervised classification used to classify data according to predefined classes. It is also used as a technique of description and analysis -generally in partnership with factor analyses- as well as a technique of reduction as the set centroids -of the classes- can be considered as representational of the entire data set. The initial method can be principally credited to Forgy (1965). The general principle of the method is aggregation around mobile centroids. This makes CbyP close –but not identical- to many classification techniques such as “the dynamic clouds” (Diday, 1974) and the k-means introduced by MacQueen (1967). In fact CbyP is some times labeled as “batch” k-means.

This function can be used when there is a target group number to obtain. Considering the user want to partition the laboratories into four groups regardless the topics they are working on, a CbyP using four centroids would be the most appropriate.

**Clustering countries according to their contribution profiles**

In this example, we considered again the same crossing table. First each year and each country has been normalized so that we obtain their profile rather than their contribution in terms of number. For example, USA is publishing regularly (comparable number of paper every year). A country that would do the same, even publishing only one paper per year would have the same profile. Figure 4 displays the results.

Australia is the closest to America regarding its profile.
5.3 Geographic maps

Principle

Geographic maps are used when geo-referenced data is handled. Geographic map agents use 2-D matrix in which one of the dimension corresponds to geo-referenced data (Karouach, 2003). As we say previously, institutes are geo-referenced data that can be defined by their spatial co-ordinates. However, in the current module, the smaller granularity of representation is the country. However, using specific databases that provide spatial co-ordinates, it would be possible to change this granularity.

To illustrate the usefulness of geographic maps in our approach, we show how they can be used in order to visualize the contribution of each country to the document set; we also show how evolution can be taken into account in this analysis. This analysis is based on authorship.

Maps to visualize the contribution of each countries

The previous section explains how an analysis can make clearer the specificity of some countries in term of topics. The relative contribution of each country is another type of information that explains how a domain is structured. Regarding our case study, it corresponds to the contribution in term of number of publications that have been
accepted at the SIGIR conference. This contribution can be analyzed globally or year by year in order to understand the evolution.

The starting point of this representation is a 2D matrix in which lines correspond to countries whereas columns correspond to the year of publication. The matrix indicates the number of publications that are written by an author from a given country for a given year. Note that publications that have two co-authors from a single country are counted only once whereas a publication that is co-authored by authors from two different countries is counted twice (one for each country).

In the screenshot figure 5, 4 years of publication are considered. The greener (brighter) a country is displayed, the more important it is (the reversed coloring is also possible, to be closer to the topographic metaphor). The scale of coloring is not linear because otherwise the only country that would have been colored would be the USA. Instead, we applied a non-linear scale so that contributing countries are colored, even if their contribution is comparatively less important. Countries that are not colored have no contribution in the analyzed set of documents.

![Figure 5: Contribution of the different countries along the entire period (1991-2002)](image)

More importantly, it can be interesting to visualize the evolution of the contribution of the countries along time. In Figure 5, the country contributions are considered whatever the year of publication is, but it is also possible to visualize only one year (or selected years). In Figure 6a) for example, year 1991 only is displayed; in the same way figure 6b displays the information for year 2002. In Figures 6, like in the figure 5, non-colored
countries have no contribution during the all period (e.g. African countries). Countries in green are the countries that contribute in the considered year and countries in red are countries that do not contribute in the considered year even if they contribute in the studied period (e.g. China contributes during the period; however this country did not contribute in 1991 but does in 2002).

From Figures 5 and 6 other interesting knowledge can be extracted: UK proportionally contributes more over the entire period than just in 2000 (the brightness of the green gives this information). This is the opposite for Finland who contributes more in 2000 than during the entire period (proportionally). In 2002, Finland organized SIGIR.

This type of analysis is useful to show the emerging countries in a domain. When combined with the previous analysis on correlation between topics and countries, the added value of such analysis is important.

a) Considering 1991 only
b) Considering 2002 only

**Figure 6:** Contribution of the different countries for one selected year.

### 5.4 Graphs

**Principle**

Graphs are among visualization tools the most used in the literature, as linking concepts or objects is the most common mining technique. Graph agents use 2-D matrix of any type resulting from the pre-treatment of the raw information and corresponding to co-occurrence matrix. A 2-D matrix can also result from a mining method. Graph nodes correspond to the values of the crossed items whereas edges reflect the strength of the co-occurrence value. Graph drawing is based on (Fruchterman, 1991). In this type of algorithms, a graph node is considered as an object while an edge is considered as a spring. Edge weights correspond to power either corresponding to repulsion or attraction between the objects that make them move in the space. This keeps the vertices moving on the visualization space until an equilibrium position is reached. Once stabilized the spring system provides the best graph drawing or node placement.

We also considered the analysis of graphs properties (Truong 2004) (Karouach 2003) such as cluster analysis for which we use spectral analysis among other methods –some of them have been discussed above. To provide ways of identifying the most influential objects –authors, countries…–, we provide centrality analysis methods such as degree,
betweenness, or proximity analysis. We are now exploring methods to conduct structural analysis of graphs like in (Kleinberg 1999) regarding hub/authority measures.

To illustrate the usefulness of graphs in domain analysis as we promote, we present in the two next sections how graphs are used to visualize collaborations at the country level (considering co-authoring) and common topics of interest of different countries (according to publication content).

**Graphs to visualize collaboration between countries**

Collaboration between countries is a source for technological activity and creativity around the world (Verbeek, 2003). Thus it is important to be able to know the countries that collaborate with each other and the strength of these collaborations (frequency). To analyze this type of collaboration, the starting point is a 2-D matrix based on the producer point of view. The same attribute is considered, but at two levels of detail: country and author levels. That is to say lines correspond to authors' names whereas columns correspond to countries. At the crossing of a line and a column, we obtain the number of publications a given author co-occur with a given country name (the country s/he belongs to or the country which a co-author belongs too). Note that in the case of multiple co-authors from the same country for a single publication, the co-occurrence is counted only once. We use the first document set for this analysis (2000 to 2003). In figure 7, countries appear in green whereas authors are displayed in red. Countries that are not correlated to other countries do not appear in this graph. That means that we only consider the publications that have at least two authors belonging to two different countries. The edges correspond to links that have been inferred between countries and authors.

Using this type of network representation, cooperation between countries appears in a single shot. For example, strong relationships are shown between China and Hong-Kong and between Israel and USA. China and Hong-Kong are not surprising considering the political point of view. Israel and USA relationships in IR are explained by the fact that a laboratory of the IBM Company is situated in Haifa (Israel) and publications are co-authored with IBM US (this can be validated when going back to the publication them-selves). The power of this representation is that links are drawn, but more importantly, the explanation of the link is given. When considering Netherlands and UK for example, the association is manly due to ‘Djoerd Hiemstra’. In the same way, the association between China and Canada is due to two persons: Jian Yun Nie (Canada) and Ming Zhou (China). The former author is from China, did is PhD
in France and has now a position at the University of Montreal, Canada. Another important link can be shown between UK and Taiwan. The authors the link is due to are also shown (one is John Tait). This link has a possible explanation. The latter author has strong links with Taiwan from a while: in 1994 a PhD student from Taiwan passed his PhD in John Tait’s group and is now in Taiwan; the authors from Taiwan and from UK co-publish since at least 1998. This information is not in the document sample that is analyzed, but came from validation from the Web and from digital Libraries.

**Figure 7: Author/Country network**

**Graphs to extract the main topics of interest of the countries**

All the countries may not evenly contribute to a domain. Some countries may be more specialists in some sub-fields (because of historical reason or because of the country support to this sub-field for example). It is useful to know if some countries have specific interests and what are the topics that are common to all the countries. This is the purpose of this part of the analysis.
In the case of figure 8, the 2-D matrix consists of lines that correspond to key words and columns that correspond to countries. Some interesting sub-networks have been circled on the figure. For example, Canada and Turkey are linked through common topics of interest and this link is not due to some publications that would have been written by an author from Canada and another from Turkey (in Figure 7 these two countries are not linked).

6 COMMUNICATION BETWEEN MINING/VISUALIZATION AGENTS

In our approach, collaboration between agents is used in two ways. When a *single user* is involved one visualization agent can use the results of a mining agent. As an example the result of a classification based on geo-reference (the objects to classify are countries) can be displayed on a geographic map. In that case, a different color will be associated with each class. In the same way, two visualization agents or two mining agents can communicate. This mechanism improves the mining process.

When several users are involved, collaboration between agents gives a way of collaboration/synergy between users. In this case, all the users analyze the same data at
the same time over the network and need to share information or exchange points of views.

6.1 Communication principle

We provide several ways of agents communication based on inter process communication. Among those ways of communication we can mention:

1. Broadcast: queries are broadcast to agents –some times filtered by specialty. This kind of communication is used for example to focus on a same object in different visualization tools.

2. Publish/subscribe: agents provide services –mainly message broadcasts- which are used by agents to those services. For example classification agents provide partition to visualization agent. An other example is 4D visualization agents that ‘exports’ their point of view –focus, rotations and zoom- to others 4D agents who explicitly register for this kind of information. This make possible for users to control each others visualization 4D of same the data compatible data set.

6.2 System architecture and agent communications

The overall architecture of the system is presented Figure 10 b) whereas Figure 10 a) details the communications between mining and visualizing agents.

As shown in Figure 10a), when activated, an agent registers it-self to the communication facilitator. This enables the facilitator to have a comprehensive overview of active agents, their state (willingness to communicate), and the data they are handling. The Facilitator also manages a database of raw data, numerical results, users captured views and it analyses annotations.

Every message that is sent to the facilitator is forwarded to active and compatible agents which are dealing with data in relation to the sender data.

Moreover, every agent has access throw the facilitator to a search engine application to provide the user with raw information about analyzed or visualized information.

Figure 10: Architecture of the system
Any visualization modules can directly visualize summarized information or it can be mined. The results of the mining modules can also be visualized using the visualization modules. Mining and visualization modules can be combined in different ways (see section 6.3).

6.3 Illustration of communication to discover information

In the previous section we indicate the importance of combining different types of analysis (e.g. contribution of the countries and correlation between countries and topics). Combining mining and visualizing tools as many applications. For example, combining graphs (e.g. networks of authors) and maps can help understanding a phenomenon (countries that are close one to another, countries that share a common language, etc…). It is also possible to combine HAC and maps to visualize countries with same publishing profiles.

In the rest of this section we depict the first example of combination: graphs and maps.

Combining networks and maps to visualize the collaborations of an author at a country level

We illustrate an efficient way to combine graphs and maps in order to understand better the location influence on author clusters.

Figure 11 depicts the co-authoring associations. Each node corresponds to an author whereas edges correspond to co-authoring association. Nodes are colored to show the importance in term of contribution of the author (number of publications in the document set). The brighter a node is, the more the corresponding author contributes. In the screen shot, we removed the author names to make the network more readable, but it is also possible to visualize the details of the nodes. One can see that clusters of authors are clearly visible, showing that there is not a lot of co-authoring. It is possible to select a sub-graph on the left-side sub-window and visualize it on the right side window. From a graph (right-side window figure 11), it is also possible to select an author. In that case, the sub-graph corresponding to this selected node is automatically extracted: it includes the nodes that have at least one connection with the selected node (it is possible to choose the level of depth in order to include the direct neighbors or the neighbors of the neighbors). Figure 12 shows the combination of the graph module and the map module. The country of the selected author appears in bright green (UK), the countries
of the correlated authors appear in darker green. Again, the countries in orange are the
countries that contribute to the document collection but in this case that are not in the
selection (none of the authors selected are from these countries).

7 CONCLUSION

In this paper, we present a method to understand the state of the art and the evolution of scientific communities and research topics. It is based on the analysis of document sets (scientific publications) from which information is extracted and mined. Our contribution is not to present new mining methods but rather to lean on existing ones. The platform we developed integrates different data analysis methods from the literature as well as different visualizing modules. After interesting attribute values are extracted from the documents, 2-D tables are built that correspond to summarized data. 2-D matrixes correspond to the input and output of the mining modules and input of the visualization modules. This makes it possible to make the modules communicate.

We illustrate our approach through a case study. Using this case study, it was not possible to present all the possibilities and combination our platform allows in order to analyze a domain (e.g. factorial analysis has not been illustrated) but we show interesting type of analysis that can be conduced using our methodology and our system. We focus on geo-referenced data and show different types of advanced information that can be extracted from documents. We also show how geo-reference can be combined with other meta data to provide global views on a domain. Finally, we show that maps can be combined to other visualization to provide the user with different views on the data.

Future work will concern the level of granularity the geographic map module takes into account. Currently the smallest level is the country, which is acceptable for some applications but not for all applications. Generally, a more detailed visualization is needed. Many GIS databases provide detailed information that could be included in our modules (both in the information extraction module and in the visualization module). A long term issue regarding this type of system is to define criteria of evaluation and benchmark collections as Information Retrieval community does with programs such as Text Retrieval Conference (trec.nist.gov)
